Acknowledgement

This report was prepared for the National Academy of Sciences (NAS) as part of their prime contract with the National Highway Traffic Safety Administration (NHTSA) to assess fuel consumption technologies for medium and heavy duty vehicles. The Transportation Research Board’s Division on Engineering and Physical Sciences was responsible for this work and assigned the effort to the Board on Energy and Environmental Systems. The project identifier is BEES-J-08-A. The NAS project director was Mr. Duncan Brown and the ANL principal investigator was Phil Sharer. Dr. Andrew Brown, Jr. chaired the NAS committee, initiated the project, and provided valuable guidance to help direct and focus ANL’s research along with the other members of the committee.

We would also like to thank all the companies who provided state-of-the-art component data and control logic to allow proper modeling and simulation of numerous medium and heavy duty trucks applications.
1 Introduction

The main objective of this report is to provide quantitative data to support the Committee in its task of establishing a report to support rulemaking on medium- and heavy-duty fuel efficiency improvement. In particular, it is of paramount importance for the Committee to base or illustrate their conclusions on established models and actual state-of-the-art data.

The simulations studies presented in the report have been defined and requested by the members of the National Academy committee to provide quantitative inputs to support their recommendations. As such, various technologies and usage scenarios were considered for several applications. One of the objective is to provide the results along with their associated assumptions (both vehicle and drive cycles), information generally missing from public discussions on literature search. Finally, the advantages and limitations of using simulation will be summarized.

The study addresses several of the committee tasks, including:

- Discussion of the implication of metric selection
- Assessing the impact of existing technologies on fuel consumption through energy balance analysis (both steady-state and standard cycles) as well as real world drive cycles
- Impact of future technologies, both individually and collectively
2 Assumptions

2.1 Data Collection Process and Sources

The vehicle configurations and technical specifications described below were gathered from different sources. Various collaborations with component and vehicle manufacturers as well as literature review were considered. Although eight vehicle applications were modeled, only four of them were actually simulated due to time constraints and greater interest from the Committee. Therefore, we will only provide the assumptions for these four vehicles: Pickup Truck (Class 2b), Utility Truck (Class 6), Transit Bus (Class 8) and Line Haul Truck (Class 8).

2.2 Vehicle Model Description

The Powertrain Analysis Toolkit (PSAT), developed by Argonne National laboratory, has been used to perform the vehicle simulations. PSAT is a forward-looking simulation package (also called driver-driven). A driver model follows any standard or custom driving cycle, sending a power demand to the vehicle controller, which, in turn, sends a demand to the propulsion components. Component models react to the demand and feed back their status to the vehicle controller, and the process iterates to achieve the desired result. Each component model is a Simulink/Stateflow box, which uses the Bond graph formalism.

The components boxes are then “assembled” according to the powertrain configuration chosen by the user in the Graphical User Interface (GUI).

Figure 1: Example of Vehicle Model in PSAT
The user-friendly GUI (Figure 2) allows the user to build a vehicle model within a few minutes.

First, the user selects the drivetrain configuration. Each configuration is built according to user input so that vehicle architectures can be compared and the most appropriate one selected. More than 300 pre-selected configurations are available. Secondly, the user selects a model for each powertrain component, its initialization file, and tunes the initial parameters. Similarly, the controller strategy is chosen and tuned. The user then selects the combination of cycles to be simulated, and finally launches the simulation. Once the simulation is completed, the GUI provides the user with a wide range of plots and calculation, particularly useful for analysis.

![Figure 2: PSAT GUI Example](image)

The plant models used in the study were based on steady-state lookup tables to represent the losses. The shifting algorithm and vehicle level control logics have been developed to be adapted to any combination of components and validated for several applications with OEMs. All the results are provided for hot operating conditions.
2.3 Vehicle Specifications

2.3.1 Pickup Truck Class 2b

Because this vehicle class is close to its light duty counterpart (Class 2a), the assumptions used were all derived from the literature. The amount of information for this application was widely available.

The assumptions for the Pickup Truck were based on the GMC Sierra 2500 HD [1]. This vehicle has a Gross Vehicle Weight (GVWR) of 4172 kg and consequently belongs to the class 2b. Furthermore, as shown later in paragraph 7.2, this particular pickup also offer the advantage of offering specifications for both gasoline and diesel configurations. Table 1 summarizes the main assumptions used. The engines specified by the manufacturer were not available in the modeling and simulation database. As such, the Cummins ISB 6.7L and the GM LM7 5.3L were selected as alternatives. For more details about how these engines were scaled to match the manufacturer specifications, please see paragraph 7.2. Unless specified, the pickup truck class 2b was simulated with the diesel engine.

Table 1: Pickup Truck Class 2b Assumptions

2.3.2 Utility Truck Class 6

The following assumptions for the Utility Truck class 6 are based on the GMC C-series CSC042 2WD regular cab. As for the pickup truck class 2b, this brand and model of truck has the advantage of being produced with both gasoline and diesel options, which will be used later in paragraph 7.2. The Cummins ISB 6.7L for diesel and the GM LM7 5.3L were used and scaled to match specifications. The vehicle losses specifications (drag coefficient and frontal area) were derived from the PACCAR T270 truck. Unless specified, the Utility Truck class 6 was simulated with the diesel engine.

2.3.3 Transit Bus

The assumptions shown below for the transit bus application are all based on the 40 ft Orion V model. The curb weight was set to 13061 kg (28800 lb) and the GVWR to 18412 kg (40,600 lb) as specified by the manufacturer.

2.3.4 Line Haul Class 8

The Line Haul class 8 truck was designed through collaborations with component and vehicle manufacturers. The baseline truck which was used to collect component data was a Kenworth T660 with a GVWR of 36280 kg (80,000 lb). This model of truck is equipped with a Cummins ISX 14.9L engine.
available in the PSAT database. A 10 speed manual transmission was selected due to its wide usage for the application.

Table 4: Line Haul Class 8 Truck Assumptions
3 Model Validation

The purpose of this chapter is to provide examples of vehicle validation using PSAT for the applications considered. While additional validations have been performed in collaboration with manufacturers, the results could not be shared to the proprietary information.

3.1 Line Haul Class 8 Model Validation

3.1.1 Class 8 Validation with West Virginia University

A model of a 1996 long haul Peterbilt, tested at West Virginia University, was developed and validated. Figure 3 shows the Peterbilt truck used in this research. Table 5 presents the details of the vehicle configuration.

![Peterbilt Truck](image)

</table>

As for any validation, the critical aspect is to match the efforts and flows of the different components along with the fuel rate at every sample time of the test. Figure 4 show a good correlation between the instantaneous fuel rates from simulation and test.

Table 6 shows the summary of the fuel consumption results for the test conditions considered.
3.1.2 Class 8 Validation with U.S.EPA

Another long haul application was validated in collaboration with the U.S. Environmental Protection Agency. The vehicle, tested at SouthWest Research Institute (SwRI) was modeled in PSAT and validated using dynamometer test data. The truck is a Navistar ProStar with a Cummins ISX ST400 and a 10 speed manual transmission from EATON.

Figure 5 shows the close correlation between the simulated and measured engine speed. The other components effort and flow were matched as well resulting in good comparison for the fuel economy for several cycles as shown in Table 7.

3.2 Comparison between PSAT and Published Studies

Since a large portion of the study focuses on evaluating the impact of several technologies on fuel consumption, in this section, we will vary a few parameters that are essential to fuel consumption...
reduction and compare the results with other published studies. Additional simulations will then be performed to (a) verify some published values form the literature as well as (b) generate new analysis to generate values for missing applications or technologies.

3.2.1 Weight Reduction

Simulations were performed to assess the impact of GVWR reduction on fuel consumption. The baseline truck had a GVWR of 36280 kg. The vehicle was simulated for different weight on the HHDDT65 drive cycle which combines the various HHDDT cycles developed by the CARB [2]. The fuel consumption results and the percentage of fuel saved are shown below along with estimates by SwRI in the NESCCAF study (Presentation to NAS - December 4 2008).

![Figure 6: Impact of Gross Vehicle Weight Reduction on Fuel Consumption for a Class 8 Truck](image)

The simulations show a 9.6% fuel consumption reduction when decreasing the GVWR from 80,000 to 65,000 lb. In other terms, we can expect a 0.6% fuel saving for every 1,000 lb weight reduction. In comparison, the NESCCAF study estimates were 0.5% and the Smartway ones 0.4%. However, it is important to keep in mind that the use of different engine maps, transmissions, shifting schedules, drive cycles or accessories can affect these estimates.

3.2.2 Rolling Resistance and Aerodynamics Reduction

Simulations were performed to assess the impact of drag coefficient reduction on fuel consumption. The baseline truck is a line haul class 8 with a GVWR of 36280 kg, a drag coefficient of 0.63 and a rolling resistance coefficient of 0.0068. As for the previous paragraph, the truck was simulated on the HHDDT65 cycle and the simulation results were compared with other studies.
Figure 7: Impact of Drag Coefficient Reduction on Fuel Consumption (Rolling Resistance fixed at 0.0055)

Figure 8: Impact of Drag Coefficient Reduction on Fuel Consumption (Rolling Resistance fixed at 0.0045)
Figure 7 depicts the set of simulations which used a fixed rolling resistance of 0.0055. The drag coefficient varied from 0.63 to 0.4. Results show that reducing the drag coefficient from 0.63 to 0.5 lead to a 15.2% fuel consumption reduction. In comparison, the NESCCAF study indicated 14% fuel savings for the same scenario.

Figure 8 shows a more aggressive scenario as the rolling resistance value is set to 0.0045 and the drag coefficient is then lowered from 0.63 to 0.3. In this case, reducing the drag coefficient from 0.63 to 0.4 leads to a 26.7% fuel consumption reduction. Again, these results are close to the NESCCAF estimates which indicated 24.6% fuel savings for this situation.

### 3.2.3 Improved Transmission

Using a line haul class 8 truck, we studied the impact of increasing the number of transmission gears on fuel consumption. Based on two existing class 8 truck configurations, we simulated two vehicles were equipped with a 10 speed manual and an 18 speed manual transmission respectively. The drive cycle used was the HHDDT65 and the trucks were simulated at a GVWR of 36280 kg. The results are shown in Table 8.

</tbody>
</table>

The simulations resulted in no significant changes in fuel consumption. This study is very sensitive to the shifting logic design and to the use of a drive cycle including grade. Indeed, by tuning the shifting control parameters to ensure that the 18 speed shifts at lower engine speeds than the 10 speed, the fuel saving could reach 1 to 2%. Estimates collected from OEMs by TIAX mentioned a 1 to 5% fuel consumption reduction which is in the same range as the simulation predictions.
4 Importance of Metrics

4.1 Limitations of Traditional Fuel Economy Measurements

The use of fuel economy versus fuel consumption is very often discussed for light duty vehicles. Due to its inverse relationship with fuel consumption, fuel economy fails to accurately represent the actual saving in fuel. The main issue using fuel economy is that a 10 mpg reduction will not be translated in the same amount of fuel saving if the original value was 40 or 20. The use of fuel consumption is thus often recommended especially for a comparison between several vehicles. However, for heavy duty vehicles even fuel consumption itself has some limitations that are discussed below.

Four different vehicles are considered: pickup class 2b, utility class 6, transit bus and line haul class 8. Each vehicle is simulated on its specific drive cycle at two different payloads: 10% payload and GVWR. The following table summarizes the simulation assumptions.

Table 9: Vehicle Applications, Cycles and Weight Assumptions used in Metric Study

Figure 9: Comparison of Fuel Economy and Fuel Consumption

On Figure 9, we represented both fuel economy in mile/gallon and fuel consumption in gallons/100miles for the four vehicle applications. The two extremities of the blue bar are for the 10% payload and GVWR simulations. One notices that from one vehicle class to another, the fuel efficiency
differences are not clearly shown. For example, when looking at the fuel consumption plot, it appears that the class 6 and class 8 truck are as fuel efficient. However, these two vehicles do not realize the same work, i.e. they do not carry the same weight. Furthermore, when considering the class 2b application, the impact of driving with 10% payload or at GVWR is not significantly emphasized since the bar on the fuel consumption plot is almost reduced to a single point. Consequently, the use of payload becomes necessary to fairly and accurately measure fuel efficiency and compare heavy duty vehicles.

4.2 Introducing Payload in Fuel Efficiency Measurements

Using the same vehicle simulations as for the previous paragraph, we will now represent the results using payload fuel economy (mpg multiplied by the payload weight) and load specific fuel consumption (fuel consumption divided by the payload weight). The units are respectively “ton.mpg” and “gallons/100miles/ton” using metric tons.

![Comparison of Payload Fuel Economy and Load Specific Fuel Consumption](image)

The trend shown in Figure 10 is completely different than what was depicted on Figure 9. The fuel consumption variations due to different payload are now clearly described. For example, according to the load specific fuel consumption (LSFC) graph (on the right), the transit bus is almost 10 times more fuel efficient when fully loaded than when carrying 10% load. The line haul class 8 truck is now the most fuel efficient vehicle among the four applications as the amount of fuel consumed in regard to the load carried is the best. These four applications can now be fairly compared by taking the payload into consideration when measuring their fuel efficiency.
Figure 11 compares the fuel economy and LSFC for different payloads. In this case, a class 8 line haul truck was simulated at various weights (0, 10, 20, 30...90, 100% payload) on the HHDDT65 cycle and its fuel economy as well as its LSFC were reported on the graph. Note that in order to avoid division by zero, the LSFC starts at 10% payload. When solely looking at the fuel economy, the graph analysis would tell us that carrying an empty trailer or the full load would only have a change of 25% in the fuel efficiency. However if LSFC is considered, the change in fuel efficiency between 10% load and GVWR is nearly 90%. This better depicts the impact of the payload on the efficiency of the work done by the truck.
5 Energy/ Power Flow Analysis

To improve the fuel consumption of specific vehicles, one needs to understand the origin of the losses throughout the drivetrain for different operating conditions (e.g., speed, grade). This paragraph describes the methodology used to generate the energy / power flow analysis for several applications on both steady-states and drive cycles. While the process is described below for a specific example, the complete set of results is provided in Appendix 1.

5.1 Steady-state

All heavy-duty vehicles classes described in section 2.3 were simulated and analyzed at various steady-state speeds and loads. Even though the simulations included an acceleration phase to avoid initialization issues, the numerical values provided are solely based on the steady-state part of the cycle, during which the vehicle speed is constant. The speed ranges simulated ranged from 20 to 50 mph for the bus, 30 to 70 mph for the class 2b and class 6, and 50 to 70 mph for the class 8. The load, meaning the payload, is hereafter expressed in percentage of the maximum payload. 0% means that the simulation vehicle weight is the weight of the empty vehicle, while 100 % means the GVWR.

An example of power flow diagram is displayed on Figure 12. Average power, an intensive physical property, is preferred to simply energy, an extensive physical property. In the case of a steady-state, the average power is also the instantaneous power. The diagram can simply become an energy balance by multiplying the average power by the trip time, or an energy consumption balance by dividing the average power figures by the average speed. For example, in the case of Figure 12, the engine input average power is 395 kW, which at 65 mph average speed is equivalent to 395/65 = 6 kWh/mi.

A block represents a power converting component (engine, motor, transmission or axle), an accessory (mechanical or electrical) or a loss due to the interaction with environment (tires/rolling resistance, aerodynamic drag). For an automatic transmission (class 2b, class 6, bus), the “transmission” block encompasses the gearbox and the torque converter. “Axle” includes the final drive(s) and the transfer case when there is one (class 8).

The arrows represent the power flow; their width is proportional to the energy/ average power exchanged, though arrow sizes are not comparable between different power flow diagrams. Horizontal arrows represent exchanged flows between blocks, while vertical ones represent losses. The leftmost arrow which is the input to both the engine and the entire system represents the power contained in the fuel. Each block contains a “%Loss” value, which represents the contribution to the total losses (i.e. ratio of component loss to engine input), as well as efficiency for power converting devices.
Figure 12: Power Flow Diagram for a Class 8 Truck (Steady-State, 65 mph, 70% load)

Various power flow diagrams are available in Appendix A.

Other diagrams are available to analyze the sensitivity to load, speed or application. For example, Figure 13 illustrates the impact of speed on the repartition of losses. Pie charts can show the impact of load (Figure 14) or application (Figure 15, Figure 16).

Figure 13: Distribution of losses for a Class 8 Truck for Various Steady-State Speeds (70% load)

(Losses = 198 kW)

Argonne National Laboratory – Report to NAS – Contract DEPS-BEES-001 – October 2009
5.2 Standard Drive Cycles

A similar methodology can be used to analyze power flows on non-steady-speed cycles. Similarly to the steady-state diagrams, the numerical values associated to a flow represent the average power of that flow (total flow energy divided by time). A new block is however necessary, and is called “inertia”. It represents the kinetic energy the vehicle acquires when accelerating and that it loses when decelerating. Most of it is lost in friction losses during braking. A regenerative braking system, as used in hybrids, can recover part of that energy and add it back to the system. Several diagrams for various applications and corresponding duty cycles are showed hereinafter (Figure 17, Figure 18, Figure 19 and Figure 20).

6  Impact of Drive Cycles on Fuel Consumption

6.1  Impact of Real World Drive Cycles

In this paragraph, we will study the impact of real world drive cycles on fuel consumption. We will first compare this study with the drive cycles generally used for simulation and then look at the differences with steady states results from Paragraph 5.

6.1.1  Pickup Truck Class 2b

For the pickup truck application, real world drive cycles gathered by the U.S.EPA in Kansas City in 2005 were used for simulation. This set of data consists in 110 daily driving cycles recorded on various light duty car, SUVs and pickup trucks. We assumed that the driving patterns of a pickup truck class 2b were close enough to light duty vehicles to justify the use of Kansas City cycles. Only the speed as a function of time was extracted from the set of cycles. This information then became the cycle constraint to follow by the driver model of the pickup truck class 2b vehicle. The fuel consumption results are plotted on Figure 21 as well as the UDDS and HWFET cycles commonly used for this application.

![Figure 21: Fuel Consumption as a function of Average Cycle Vehicle Speed for a sample of Real World Drive Cycles for a Pickup Class 2b](image-url)
For a clearer analysis of the data, an interpolation of the Kansas City cycle simulations was also reported on Figure 21. The green and black stars represent the UDDS and HWFET fuel consumptions respectively. This graph mainly shows that by using a combination of the UDDS and the HWFET cycles we can reach the area where most of the RWDC are located (around an average vehicle speed of 30 to 35 mph). However, the fuel consumption of these two cycles taken separately or combined is still lower than the trend shown by RWDC which is a common remark.

While the correlation coefficient of the interpolation is only 0.64, the graph clearly shows a high correlation between fuel consumption and average cycle speed. The difference for a specific average speed is mainly due to the driver aggressiveness.

### 6.1.2 Line Haul Class 8

For the class 8 application, the real world drive cycles gathered for the simulations were recorded by Oak Ridge National Laboratory. The limited number of data (8 cycles) limits the analysis. An interpolation of the simulation fuel consumption results was performed but more RWDC would be needed to better attempt to characterize a trend between average cycle vehicle speed and fuel consumption.

![Figure 22: Fuel Consumption as a function of Average Cycle Vehicle Speed for a sample of Real World Drive Cycles for a Class 8 Truck](image-url)
As shown in Figure 21, the fuel consumption on the HHDDT65 cycle is lower than the RWDC with a similar average cycle vehicle speed. This is the same conclusion as for the pickup truck class 2b. Note that the correlation coefficient of the interpolation is only about 0.66 and shows that more RWDC would be necessary to get a better fitting.

6.2 Issues Following the Trace

One of the many challenges of heavy duty vehicle modeling is to select a drive cycle that can be driven by most configuration of a vehicle class including different weights, transmissions, etc... This can indeed become a crucial issue especially for class 8 trucks where manual configurations are widely available and weight can dramatically vary (from a 10% load to GVWR). For an 18 speed manual transmission for example, the typical average shifting time is around two seconds and the shifting events are extremely frequent. On the other hand, automatic transmissions have little power interruptions and a lower gear number. Consequently, if we compare both transmissions on the same drive cycle, with the rest of the powertrain being identical, the vehicles might not follow the trace similarly.

![Figure 23: Automatic vs. Manual Transmission for a Class 8 Truck](image)
Figure 23 clearly depicts this issue. On this graph, we show the beginning of the HHDDT65 drive cycle (in blue) as well as the vehicle speed of a manual (red) and automatic (green) class 8 truck attempting to follow this trace. The multiple shifting events of the manual truck moves the vehicle speed away from the trace whereas the automatic truck better follows the speed demand. Consequently, if we compare the simulation results for these two trucks, the manual vehicle has a better fuel consumption than the automatic because it has a lower average speed throughout the cycle since it does not follow the same trace. Therefore, there is a need of introducing an additional parameter in the fuel efficiency results: the average cycle vehicle speed.

6.3 Potential Approach to Representing Fuel Efficiency

This paragraph shows a graphical example of how fuel efficiency could be represented for regulatory purposes and in order to fairly compare different truck configurations within the same vehicle class. The steady state results simulated for the line haul class 8 in paragraph 5 are used and plotted on Figure 24.

![Figure 24: Fuel Consumption as a function of Steady State Vehicle Speeds for different Payloads](image)

Figure 24 gives an original approach to decide what fuel consumption to expect from a class 8 truck according to its cycle average vehicle speed and the weight of load carried. Taking the previous example
of the manual and automatic transmission class 8 trucks simulated on the HHDDT65 cycle, we could determine what fuel consumption such trucks should achieve according to their cycle average speed. This would lead to two different values since they did not follow the trace similarly. If the truck with an automatic transmission loaded at GVWR completed the HHDDT65 at an average speed of 60 mph, the 100% load curve on Figure 24 would then indicate 16 gallons/100miles fuel consumption for this particular truck. On the other hand, if the truck with a manual transmission completed the same cycle at an average speed of 58 mph, the same curve would indicate 15.5 gallons/100miles. Consequently, these two trucks will not have the same criteria to meet for regulation and the truck with the manual transmission might not be the most fuel efficient one even if its fuel consumption value is lower.

The question brought by the previous paragraph is: how accurately can steady states predict fuel consumption? To answer this we will take the same graph as Figure 24 but for a pickup truck class 2b and we will merge it with the RWDC fuel consumptions data (see paragraph 6.1.1). The resulting plot is shown on Figure 25.

![Fuel Consumption as a function of Average Cycle Vehicle Speed for RWDC and Steady States for a Pickup Truck Class 2b.](image)

As expected, steady states are showing better fuel consumptions than RWDC for the same average vehicle speed. However, the difference is not dramatic and the trend between the steady state curves and the RWDC interpolated curve is similar.
7  Impact of Single Technologies on Fuel Consumption

In the following sections, the impact of several technologies on fuel consumption will be assessed, including:

- Aerodynamics
- Fuel
- Hybridization

7.1  Aerodynamic

7.1.1  Utility Truck Class 6

The configuration used for the Utility Class 6 Truck had the following specifications:

Table 10: Utility Class 6 Truck Vehicle Assumptions for Drag Coefficient Study

<table>
<thead>
<tr>
<th></th>
<th>Simulation 1</th>

<td>0.55</td>
</tr>
</tbody>
</table>

Six different steady state speeds along with several driving cycles were chosen to represent various driving conditions. The Truck UDDS represents urban type driving and the HTUF cycle is similar to the light duty UDDS cycle. Finally, the HHDDT Cruise and High Speed were developed by CARB and are both highway cycles with an average vehicle speed of 40 mph and 50 mph respectively.

Table 11: Utility Class 6 Truck Drive Cycle and Steady States Assumptions for Drag Coefficient Study

<table>
<thead>

</tbody>
</table>

The simulation results are shown on Figure 26. Fuel consumption is shown in gallons/100miles as a function of average vehicle speed. Note: the fuel efficiency results for steady states were computed by removing the acceleration part which leads to the steady state, ensuring that the results are pure
steady states. The lines represent the steady states (plain for Cd=0.55 and dotted for Cd=0.7) and the scattered points (circles for Cd=0.55 and x for Cd=0.7) depict the drive cycles.

Figure 26: Impact of Drag Coefficient on Class 6 Fuel Consumption for various Drive Cycles and Steady States.

Figure 26 shows that the fuel consumption values from steady states and drive cycles are much closer to each other when the average vehicle speed of the cycle is high (>40 mph) whereas they widely differ in low average vehicle speed areas. This is understandable considering that most of the drive cycles with an average vehicle speed of 40 mph or higher usually represent highway driving and consequently do not have much acceleration / deceleration. On the other hand, a drive cycle with a low average vehicle speed (e.g., 25 mph) characterizes an urban cycle with multiple transient phases leading to higher fuel consumption than a steady state cycle at the same speed.

Figure 27 shows the percentage of fuel consumption reduction when the drag coefficient is lowered from 0.7 to the 0.55 for drive cycles and their associated steady state speed. The values were generated by taking the average speed for each of the four cycles and calculated the steady state fuel consumption values corresponding to the speed by intersecting the lines from Figure 26.
In Figure 27, it appears that the drag coefficient reduction has consistently a greater impact on the fuel consumption of drive cycles than the one from steady states. However, the difference seems to be greater at average vehicle speeds between 25 and 45 mph than at low and high speeds. The benefits from aerodynamics being related to the cube of the vehicle speed, any higher speed portion above the average will decrease the fuel consumption. Since higher speed variations are seen for lower average speeds, the difference between Steady State and drive cycle is greater at average speeds.

7.1.2 Line Haul Class 8

The configuration used for the Line Haul Class 8 Truck has the following specifications:

| Table 12: Line Haul Class 8 Truck Vehicle Assumptions for Drag Coefficient Study |
|---------------------------------|----------------------|----------------------|
|                                  | Simulation 1         | Simulation 2         |
| GVWR                             | 36280 kg             |                      |
| Simulation Vehicle Mass          | 29931 kg             |                      |
| Rolling Resistance               | 0.007                |                      |
| Drag Coefficient                 | 0.6 0.5              |                      |
Six different steady state speeds and driving cycles were used to represent various driving conditions. As for the Utility class 6 vehicle, the Line Haul is simulated on the Truck UDDS cycle as well as the three HHDDT cycles developed by CARB.

Table 13: Line Haul Class 8 Truck Drive Cycle and Steady States Assumptions for Drag Coefficient Study

<table>
<thead>
<tr>

</tbody>
</table>

The simulation results are shown on Figure 28. The lines represent the steady states (plain for Cd=0.5 and dotted for Cd=0.6) and the scattered points (circles for Cd=0.5 and x for Cd=0.6) depict the drive cycles.

Figure 28: Impact of Drag Coefficient on Class 8 Fuel Consumption for various Drive Cycles and Steady States.
As shown in Figure 28, fuel consumptions achieved during steady states are closer to one from the drive cycles when the average vehicle speed is higher than 40 mph.

![Comparison of Aerodynamics Fuel Savings for Cycles vs Steady States](image)

In Figure 29, the same conclusions as for the class 6 utility truck can be drawn. However another interesting point can be made. Except for the lowest vehicle speed drive cycle, both trucks were simulated on the same cycles but the fuel savings vary widely from the class 6 to the class 8. For example, the class 6 truck reduced its fuel consumption by more than 14% on the HHDDT cruise against only 6% for the long haul. This difference is due to the similar aerodynamic specifications of these trucks taking into consideration the weight discrepancy (9 tons vs 30 tons). The aerodynamic losses representing a greater percentage of the overall powertrain losses for the class 6, the drag coefficient reduction will have a greater impact on the vehicle fuel efficiency.

### 7.2 Type of Fuel

This paragraph explores the impact of using either Gasoline or Diesel fuels for two vehicle applications: the pickup truck class 2b and the utility truck class 6.
7.2.1 Pickup Truck Class 2b

7.2.1.1 Assumptions

The GMC Sierra 2500 HD pickup truck was selected since both gasoline and diesel engines were available. Table 14 shows the main specifications [1]:

<table>
<thead>
<tr>
<th></th>
<th>Diesel</th>
<th>Gasoline</th>
</tr>
</thead>

<td>245/75R16</td>
</tr>
</tbody>
</table>

Since the latest Duramax and the Vortec engines are not available in PSAT, similar engines were used and scaled to match the specifications. The Gasoline engine is a GM V8 LM7 5.3L with overhead valves, two valves per cylinder and sequential fuel injection which offers very similar specifications than the Vortec engine in terms of rated maximum torque and power [5]. The closest available diesel engine was a Cummins ISB 6.7L calibrated for vehicle test procedure purposes (i.e. suitable for a class 2b pickup truck contrary to other heavier duty versions of the ISB engine calibrated for emissions). The engine power and torque curves of the Duramax can be found in the literature [3].

The power and torque curves of the Cummins ISB being proprietary data, they will not be shown in the report. However, we can mention that after scaling, the engine had a peak torque of 940 Nm at 1600 rpm and a peak power of 272 kW at 2950 rpm. No cylinder deactivation technology was considered for this study.

7.2.1.2 Simulation Scenarios

Two different sets of simulations were completed for this vehicle:

- **Scenario A**: The first scenario uses the peak power values found in the literature for the two GMC Sierra versions (272 kW for diesel and 268 kW for gasoline).
- **Scenario B**: The second scenario uses an automated sizing algorithm to ensure that both vehicles have the same performance specifications. Using the diesel as a reference, we simulated an acceleration test from 0 to 60 mph. The gasoline vehicle was then designed to match the performance. Note: the diesel vehicle takes into consideration a 6% penalty in
acceleration time due to turbo lag. The vehicles achieved the acceleration test in 9 seconds and the resulting engine powers were 272 kW for diesel and 276 kW for gasoline.

### 7.2.1.3 Simulation Results

Four different drive cycles were used to offer various aggressiveness conditions. Due to the similarities with light duty pickup truck, the UDDS, HWFET, LA92 and US06 cycles were selected. All vehicles were simulated at gross vehicle weight.

Table 15 shows the fuel consumption for the two vehicles according to the different scenarios. All values are in gallon/100miles and unadjusted. For the diesel vehicles, the first value is volumetric fuel consumption (gallons of diesel consumed per 100 miles) and the second one in parenthesis is in gasoline fuel consumption equivalent.

The amount of fuel saved by a diesel pickup truck compared to its gasoline counterpart ranges between 19.2 to 27.5% when comparing volumetric fuel consumptions (9.1 to 19.5% when in gasoline equivalent). The trend showed by the different cycles is that the more aggressive/faster the driving pattern, the greater the advantage of diesel.

These results could seem lower than the common Diesel/Gasoline comparison for light duty vehicles (commonly used value of 30% for volumetric fuel consumption). In this case, the two class 2b trucks were simulated at GVWR. However, these vehicles are designed to be able to tow an additional 10,000 to 15,000 lb trailer. Consequently, both engines did not operate at full load since the simulation did not require so. Both engines are operated at low loads (typically lower than 200 Nm) where their efficiency maps are similar. These are the typical conditions observed on the UDDS cycle which explains why the fuel consumption advantage of the diesel is only around 19%. On the other hand when the engine is operated at higher loads (more than 200 Nm), the diesel engine operates a higher efficiencies than for the diesel engine. As a consequence, the US06 cycle shows a greater fuel consumption advantage for the diesel engine (around 28%).
7.2.2 Utility Truck Class 6

7.2.2.1 Assumptions

The GMC C-series C5C042 2WD regular cab was selected since both gasoline and diesel engines were available. Table 16 shows the main specifications [4]:

As for the pickup Class 2B application, we used the GM LM7 5.3L gasoline engine since it is the closest data available in the PSAT database. For diesel, we used a Cummins ISB 6.7L engine calibrated for
engine dynamometer certification and thus not the same version as for the pickup truck. The gasoline engine was scaled to match the peak power specification. For the Cummins ISB diesel engine was scaled as well. The original power and torque curves as they are defined for this GMC truck for the two engines can be found in the literature [3].

7.2.2.2 Simulation Scenarios

For the Class 6 vehicle, a single simulation scenario was used. The engine peak power was directly derived from the GMC truck used as a reference. The value of 240 kW was used for the gasoline engine peak power and 246 kW for the diesel one.

7.2.2.3 Simulation Results

Three drive cycles were used for simulation: the HTUF Pickup and Delivery Class6, HHDDT65 and the Truck UDDS. The vehicles were run at a GVWR of 26,000 lbs (11,791 kg). The following table shows the fuel consumption results in unadjusted gallons/100miles. For the diesel vehicles, the first value is in Diesel fuel consumption and the second one in parenthesis is in Gasoline fuel consumption equivalent.

The amount of fuel saved by the diesel configuration compared to the gasoline is 26% on average for volumetric fuel consumptions (around 17% when in gasoline equivalent). This value is closer to the common Gasoline/Diesel comparison accepted for light duty vehicles. Indeed, a quick ratio of the engine map peak efficiency would give a 16% advantage for the diesel engine. In the case of the class 6, the engine is operated closer to the full load and to its peak efficiency more often.
7.3 Tractor-trailer Hybridization

7.3.1 Hybridization Principles

Hybrid electric vehicles have demonstrated their ability to significantly reduce fuel consumption for several medium and heavy duty applications. While much work is available in the literature for buses, delivery truck or utility trucks, little information is available for long hauls. This section focuses on analyzing the hybridization potential of several powertrain configurations for Class 8 long haul.

Most of the energy losses occurring in a truck come from the engine. On a urban cycle, the engine average efficiency is only 37 %, which means the engine could be operated more efficiently. On the other hand, on the highway there is less opportunity for improvement as the engine is already operated close to its peak efficiency (41 % average). Operating the engine more efficiently can be achieved mainly in two ways: not using the engine at all during those low efficiency operation moments, or shifting the operation point to a more efficient level – for example by increasing the engine output and storing it an energy storage system, or by decreasing the engine speed.

The losses due the tires and aerodynamic losses cannot be displaced by hybridization, since the vehicle follows the same cycle, and requires the same amount of power regardless of the source of power. The losses due to the driveline could be in part displaced if the electric power source is put
closer to the wheels (e.g. series w/o transmission, post-transmission parallel, in-hub motors, etc.), but that is not a practical solution for heavy-duty applications.

The accessory load can be affected by hybridization, as some of the mechanical accessories (pumps, compressors, etc.) can be replaced by electric systems. This is a difficult exercise to replicate in simulation, as it requires the knowledge of the mechanical accessory load in both conventional and hybrid case. In this study, some of the load is displaced from mechanical to electrical.

A conventional vehicle also loses much of the kinetic energy it acquired during acceleration through friction when braking. A regenerative braking system can recover part of this energy and recharge the energy storage system, and that energy can in turn be used for the accessory load and/or for propulsion.

Hybridization could lead to other indirect fuel savings opportunities, that are not necessarily well represented in a cycle-type testing procedure (either actual on a dynamometer or in simulation). If performance (meaning here higher acceleration capability) is improved or shifting time is reduced, the vehicle will be less likely to “lose” the trace – i.e. the vehicle speed dropping below the target trace speed – and will not need to accelerate as much later, while performing more “work” (higher distance). On the other hand the availability of improved performance can lead the driver to request more power in real-world driving conditions, possibly leading to a less efficient use of the hybrid system.

7.3.2 Hardware Design

7.3.2.1 Hybrid Configurations Overview

A hybrid vehicle can have one or more electric machines that can be positioned at various points of the powertrain, leading to a large number of configurations. The main configuration families are presented hereinafter.

**Series.** In a series configuration, the vehicle is only propelled by electrical power. The engine output power is converted into electricity through a generator and then is either stored in the battery or converted back into mechanical power by the propulsion motor. The latter can be directly connected to the final drive, or to a gearbox with a lower number of gears than a conventional one thanks to high torque availability at low speed and increased motor speed range. This configuration is generally the easiest to implement because the propulsion is 100 % electric, while the generator set is almost an independent system, relatively easy to control. A drawback of this configuration is that both electric machines have to be oversized: the propulsion one to the vehicle power/torque requirements, and the generator to the engine power. Another drawback is that at cruising speed the de facto electric transmission has a poor efficiency due to the double conversion of engine mechanical energy. One note that variations of series configurations are currently trying to address this limitation.
**Parallel.** In a parallel configuration, the vehicle can either be propelled directly from thermal or electrical power. The vehicle usually has at least one clutch and a multispeed gearbox close to a conventional model. That means the engine-to-wheels path goes through the gearbox, in a similar fashion to a conventional powertrain, thus resulting in a relatively good efficiency at cruising speeds. The electric machine can either provide positive torque, contributing to the propulsion of the vehicle, or recharge the energy storage by diverting part of the engine torque. There are several variants of the configuration, based on the position of the electric machine.

In a starter-alternator position, the electric machine is between the engine flywheel and the clutch; when the clutch is open, the motor is disconnected from the drivetrain. This configuration is used in micro-hybrids or mild-hybrids allowing the engine to be shut down at idle, and quickly started again when the driver requires the vehicle to start moving. Its main advantage is its ease of implementation and cost effectiveness. However expected gains are limited by the level of regenerative braking.

In a pre-transmission, the electric machine is between the clutch and the gearbox. In a post-transmission, the electric machine is between the gearbox and the final drive (or transfer case). When the clutch is open the engine is disconnected from the drivetrain, while the electric machine is not, therefore allowing an electric-only mode. In the pre-transmission case, the electric machine benefits from the gearbox torque multiplication, which provides more freedom in terms of electric machine speed range choice, and ensures that the electric machine can be operated above its base speed most of the time. On the other hand, in the post-transmission case, the motor-to-wheels path is more efficient as it does not include the transmission; also there is no torque interruption during shifting. For both pre- and post-transmission configurations, the clutch control is often a challenging engineering problem.

**Series-parallel.** This configuration combines the benefits of the series and parallel pre-/post-transmission configurations. When the clutch is open, the engine can be off or can be on and generate electricity through the generator, creating a series path. Generally the series-path is used at low speeds, while parallel is chosen for higher cruising speeds. The series-parallel can be combined with gearboxes with a lower number of gears.

**One mode power split.** This configuration is used by Toyota (e.g., Prius) and Ford (e.g., Escape). The engine and a motor-generator are connected to a planetary gearset, to the output of which another electric machine is connected. In this configuration, the engine power is split: part of it is transferred to the wheels, while another goes through the electrical path, with a double energy conversion, similar to the series. The planetary gearset and the electric machines act as an electric-variable transmission (EVT). The engine speed can be chosen relatively independently from the vehicle speed; the control can therefore choose to consistently operate the engine in an efficient area. At cruising speed, the EVT may not be as efficient as a conventional gearbox, depending on the level of recirculation. Furthermore, this configuration leads to significant oversizing on heavier vehicles in order for them to be able to operate in a broad range of operations.
Multi-mode transmission. A multi-mode transmission combines several power-split modes, each of them suitable for different operational requirements, therefore avoiding component oversizing. It can also be combined with fixed gear(s) - adding parallel paths - for extra flexibility on grades or cruising.

7.3.2.2 Configurations selected for the study

Two hybrid configurations were selected for this study: series-parallel and starter-alternator. The conventional series configuration is not well suited for tractor-trailer applications because it is not efficient at cruising highway speeds, which is the most frequent use of such a truck. A multimode hybrid with fixed gear could be an option, but due to the complexity of its design and its control, it will not be considered in this study. The parallel pre-transmission is similar to the series-parallel.

The series-parallel with one electric machine in pre-transmission position (between the clutch and the gearbox) is chosen to be a full-hybrid, with electric-only mode capability. Thanks to another electric machine, the series mode will allow easy engine starts, as well as a recharging capability when the vehicle is stopped.

![Figure 32 – Schematic of the series-parallel configuration (full-hybrid)](image)

The starter-alternator, thanks to a low power electric machine and low energy battery is selected for a “mild-hybrid” truck, i.e. with engine shut-downs at idle and regenerative braking possible, but with no electric-only mode. Thanks to a low power electric machine and low energy battery, the mild-hybrid requires lower upfront investment than the full-hybrid option.
7.3.2.3 Component Sizing

For light-duty applications, typical sizing requirements are made of four criteria: acceleration (e.g. 0-60 mph time), passing (30 to 50 mph time), gradeability at a given speed and top speed. For a hybrid, the electric system cannot be used for the grade requirement, as there would not be enough energy to sustain a continuous grade over a long period, so the engine must be sized for that specific requirement. The electric system can however be used for the acceleration/passing requirement, because the most restrictive factor is in general the acceleration requirement, an engine downsizing can therefore be achieved — that is generally the case with production light-duty hybrids.

The same type of requirements could be applied to tractor-trailers. However, there is no industry-wide standard, as trucks are customized to fleets requirements. Another major difference between the two applications is that heavy-duty vehicles often operate at maximum power, especially during grades. From a conventional truck, no engine downsizing can be done because the battery energy limits the electric propulsion to a short duration, while grades can be long. In this study the engine size is therefore the same as in for the conventional version.

In the case of the less expensive and simpler starter-alternator, the electric machine power is set at 50 kW. For the series-parallel truck, the same size of electric machine is used for the generator (motor 2), while the propulsion electric machine (motor 1) has a 200 kW power. A electric machine power sensitivity or a design optimization study could provide a more precise choice of electric machine power, but is out of the scope of the present study.

The battery power matches the electric machine power, while the battery energy is based on hotel loads. The average load is estimated to 1.5 kW, including air-conditioning in the summer, cabin and engine block heating and various electric accessories (fridge, tv, lights, etc.). This value is based on existing literature and accessory/idle-specific devices specifications. In the case of the full-hybrid, the
battery energy is such that it can provide the 1.5 kW load for the duration of a hotel stop of 10 hours, if fully loaded at the beginning of the stop. The usable battery energy for a lithium-ion technology is 60% of its total energy (operating range between 90% and 30% of state-of-charge), resulting in a 25 kWh battery. In the case of the mild-hybrid, the battery is only 5 kWh to limit the cost of the system. It would be sufficient for a 2 hour period, after which the engine would have to be started in order to quickly recharge the battery. Since the power at which the engine would be operated would considerably be higher than during a conventional idling, this solution would still be more efficient.

For both hybrid trucks, the gearbox remains unchanged compared to the conventional. In the case of the series-parallel, the number of gears could however probably be reduced. If the truck is always operated in series mode up to a certain vehicle speed, some of the higher gear ratios can be removed, provided that the propulsion electric machine has the proper speed and torque ranges. Finding the right combination of gear number, ratio and electric machine design is a study in itself that is outside of the scope of the present study. A specific transmission is however unlikely to bring significant energy efficiency improvements, as the full-hybrid simulated here is already very efficient. A different gearbox could however reduce cost, space and improve drivability.

#### 7.3.4 Standard Drive Cycles Results

All versions of the truck (conventional, mild and full hybrid) were simulated on various standard cycles, both highway cycles (HHDDT 65, HHDDT Cruise, HHDDT high speed) and transient/urban (HHDDT Transient, UDDS Truck).

Table 20 summarizes the main characteristics of each cycle.

When testing or simulating a hybrid vehicle, it is necessary to ensure that the results are not biased by the battery energy – the test/simulation needs to be “charge balanced”. Several iterations of the same cycles were run, so that difference in battery SOC (between the start and the end of the simulation), and therefore the battery energy used become negligible.

Figure 34 shows the fuel consumption of all 3 trucks, while Figure 35 illustrates the fuel savings compared to conventional. For both hybrids, the fuel savings are lower on the highway cycles, which is to be expected since the hybrid system does not help much at cruising speeds where the engine already operates efficiently. The mild-hybrid shows fewer saving than the full hybrid, peaking at 11 %, while the full-hybrid can save up to 40% on a urban cycle.
Figure 35: Fuel Saved by hybrid trucks with respect to conventional truck, on standard cycles

Most of the gains originate in the energy recovered during braking. Figure 36 shows the fraction of the total braking energy that is recovered at the wheel – meaning not including the driveline and electric machine losses involved in the channeling of that energy into the battery. The recovery rate depends on the cycle aggressiveness during deceleration. On the HHDDT Cruise cycle, which has the lowest deceleration levels among all the cycles, the full-hybrid manages to recover almost all of the braking energy – i.e. mechanical brakes are not rarely used– but only half of it in the HHDDT 65. The mild-hybrid recovers about 25% of the braking energy on most cycles, and peaking at 55% on the HHDDT Cruise. This is due to the much lower power of the electric machine, combined with a higher torque interruption time during shifting.

Figure 36: Percentage of Braking Energy Recovered at the Wheels
The engine efficiency does however not improve significantly in most cases, as shown on Figure 37. In particular, in the mild-hybrid case, the engine efficiency is even slightly lower than in the conventional case. The main difference in engine operations between the conventional and the mild-hybrid is that the engine is shut down when the vehicle is stopped for the mild-hybrid while the operations are similar when the vehicle is moving. In addition, the mechanical accessory load is much higher for the conventional (5 kW vs. 1 kW), and additional load generally improves efficiency. For the full hybrid, the efficiency improvements are limited on the highway cycles but are significant on the transient/urban cycles, where the low efficiency operations can be replaced by electric-only mode.

![Figure 37: Average Engine Efficiency of conventional and hybrid trucks on standard cycles](image)

7.3.5 Hybridization and Grade

7.3.5.1 Description of the Study

In the previous simulations, the road driven was flat – i.e. no grade. In real-world, trucks regularly drive uphill or downhill. Driving downhill may involve braking, which can be an opportunity for fuel savings when using regenerative braking. Due to the lack of real world drive cycles that included grade, to illustrate the potential benefits of hybridization in a “hilly” terrain, idealized sinusoidal road profiles were created. The elevation of such a road is a sinusoidal function of the horizontal distance, with a “hill” period varying between 1 and 3 km. Maximum grades also vary from 0 to 4 %. All combinations of maximum grade and period were analyzed. Figure 38 shows an example of elevation change as a function of horizontal distance for roads with same maximum grades but different hill periods. The hill period can be seen as twice the approximate distance traveled between the bottom of the hill (“valley”) and the top of the hill (“summit”). The vehicle speed target is 60 mph. The maximum positive grade is achieved halfway to the “summit”, and the maximum negative grade halfway between
the “summit” and the “valley” – there is a (horizontal) phase difference of a quarter of a period between the grade and the elevation.

![Graph showing elevation vs horizontal distance for different hill periods](image)

**Figure 38: Sectional View of roads (partial) with the same maximum (3%) grade but 3 different hill periods**

### 7.3.5.2 Adaptive Control

The control described in 7.3.3 was designed to ensure proper SOC fluctuations, but on steady-states, it generally needs to be tuned to operate efficiently. For example, the default set of control parameters does not allow torque assist at higher speeds and as a result, the battery SOC increases after each downhill braking event. The control was therefore tuned so that the energy recovered downhill is spent for accessories during the entire hill and for torque assist during uphill. The tuning is generally a function of maximum grade. The strategy adopted is likely to be the optimal way of driving such a cycle as it does not involve any battery charging from the engine (except at low grades). The results may therefore be slightly optimistic for hybrids, but an intelligent controller, e.g. GPS based, should be able to come close to that solution in a real-world situation.

An illustration of the control can be seen on Figure 39 for two different maximum grade values. At time \(t=266\), the negative grade is maximal in both cases, and the electric machine can recuperate some energy from braking, all the more that the grade is intense. At time \(t=247s\), the grade is maximal and so is the level of torque assist. However, one can notice that the powers, and energies, are different from one grade to the other, while SOC is balanced in both cases.
Simulation Paradigm

A simulation performed on a time basis, as it is done in PSAT may lead in some cases to an incorrect representation of how a trip is performed – the same reasoning applies to dynamometer tests with a vehicle speed trace. When the simulation is performed based on time, the vehicle speed and grade targets are given at each time step. So long the vehicle follows the speed trace closely, the difference between what the vehicle is supposed to do (as per the cycle) and what it actually does (in simulation) is negligible, and gives a good representation of making a similar trip in real life. This is a non-issue for light-duty applications, where the vehicle is always able to meet the trace. On the other hand, heavy-duty vehicles, especially tractor-trailers, often operate close to their peak power. There are therefore more chances that the vehicle cannot follow the trace. A loss of speed relative to the trace leads to a lower travelled distance; when looking at consumption per unit of distance, this is somehow cancelled, but still different works are performed. In particular this is an issue for grades. Let’s take a simple example: let’s assume that the target speed is 90 km/h and there is a constant grade during 30s and then there is a flat portion; let us assume truck A can go uphill at 90 km/h, but truck B can go only 75 km/h with that grade. After 30 s, truck A would have climbed 750 m, and truck B only 625 m. After 30 s, both trucks go on the flat portion whereas truck B has still 125 m left to the end of the hill! In this study, the conventional truck is not able to sustain all the grades, contrary to the full-hybrid. Using the grade signal and the actual vehicle speed (from simulation), the sectional views of the roads actually performed are showed on Figure 40 for the conventional and the full-hybrid. The difference of phase is due to the acceleration part (on flat terrain) done before starting the hills: the shifting time is much shorter for the hybrid, involving little or no vehicle speed loss contrary to the conventional truck. Since the conventional truck is not able to sustain the target speed (60 mph) during the whole hill, after the time the climbing is supposed to last, the elevation gain is lower. Going downhill, the truck has no issues meeting the speed target, the elevation loss will be what it is supposed to be. As a result the conventional truck ends up lower (in terms of elevation) than the hybrid truck. After 30 km in such hills,
with a maximum grade of 4%, the conventional ends up 7 m (more than half the elevation of one hill) below where it started, while the full-hybrid is at the same level.

![Graph showing elevation versus horizontal distance for conventional and full-hybrid trucks](image)

**Figure 40: Section View of the actual trip for a conventional and a full-hybrid truck (4% maximum grade, 1 km hill period)**

The quantitative impact on fuel consumption of that is not addressed in this study, but the reader should keep in mind the uncertainty added by an inability to follow the trace.

Another uncertainty in the representativeness of this simulation is the constant speed assumptions. It may be the case that the driver will not brake downhill so that he can be at a higher speed before starting the next hill. If there is no braking, there is little or no gain to expect from hybrid models.

### 7.3.5.4 Results

Figure 41 shows the fuel consumption of the three versions of the trucks on various hills. The fuel savings achieved by both hybrid trucks are showed on Figure 42.

With a 1% grade, there is no need for the driver to brake in order to stay at 60 mph and regenerative braking is not possible, so hybridization gains are limited.

At 2% grade, there is some limited amount of braking, but even at full recuperation rate, the energy recovered is not enough to supply the energy for the accessory load. Charge balancing is hard to achieve in that mode, and charging from engine may occur, which explains the difference in trends.
At or above 2.5 %, the downhill grade is steep enough to recover enough energy for the accessory load and for some torque assist.

Above 3% grade, the mild-hybrid savings stop increasing because the additional braking energy available cannot be recovered by the small motor. For high grades, the fuel savings for the full hybrid are all the higher that the hill period is shorter. This is not due to the hybrid itself, but to the conventional, which consumes more fuel when the hill period is shorter (and elevation is lower).

Figure 41: Fuel Consumption of Conventional, Mild-hybrid and full hybrid trucks on a sinusoidal road as a function of grade (and for various hill periods).

Figure 42: Fuel savings of hybrid trucks with respect to conventional truck as a function of maximum grade (for various hill periods)
8 Impact of Combined Technologies on Fuel Consumption

The objective of this paragraph is to evaluate the impact of various technology improvement packages on fuel consumption. The objective is to demonstrate and quantify that the gain of several technologies is not the sum of the gain of each separate ones. The pickup truck class 2b was considered for the study.

<td>1513 kg</td>
<td>GMC Sierra 2500HD</td>
</tr>
</tbody>
</table>

The assumptions for the baseline pickup truck vehicle are based on the 2009 GMC Sierra 2500 HD. As previously explained, the GM LM7 5.3L was selected as an alternate gasoline engine since the Vortec 6.0L data was not available. The engine was scaled to match the Vortec specifications. Although a 6-speed automatic transmission appears to be the standard reference gearbox for a 2009 pickup class 2b, we will also consider the case of having a 4-speed automatic vehicle.

8.2 Assumptions for Technology Improvements

Since the technology improvements could have different impacts on fuel consumption whether they are applied to a conventional or a hybrid, we will consider two different paths. The first path will use a baseline conventional vehicle which will benefit of successive technology improvements (such as aero, transmissions…) with hybridization only applied at the end. The second path will start from a baseline hybrid vehicle which will also benefit of aerodynamic improvements, optimized transmissions… In the following individual technology tables, we will show both the fuel consumption reductions in
comparison to conventional and hybrid baselines. In bold are the assumptions that were used for simulation. The results were generated based on the combined drive cycle (UDDS + HWFET).

8.2.1 Vehicle Weight

Table 22: Impact of Weight Reduction alone on Fuel Consumption for the Class 2b

<table>
<thead>
<tr>
<th>Weight Reduction (kg)</th>
<th>Percent Fuel Saved for Conventional (%)</th>
<th>Percent Fuel Saved for Hybrid (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>-100</td>
<td>+1.05</td>
<td>+0.97</td>
</tr>
<tr>
<td><strong>-136</strong></td>
<td><strong>+1.39</strong></td>
<td><strong>+1.39</strong></td>
</tr>
<tr>
<td>-200</td>
<td>+2.09</td>
<td>+2.02</td>
</tr>
</tbody>
</table>

For the package simulation, we will use a weight reduction of 300 lb (about 136 kg).

8.2.2 Aerodynamics

Table 23: Impact of Aerodynamics alone on Fuel Consumption for the Class 2b

<table>
<thead>
<tr>
<th>Drag Coefficient</th>
<th>Percent Fuel Saved for Conventional (%)</th>
<th>Percent Fuel Saved for Hybrid (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.44</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>0.35</td>
<td>+2.66</td>
<td>+3.40</td>
</tr>
<tr>
<td><strong>0.34</strong></td>
<td><strong>+2.98</strong></td>
<td><strong>+3.81</strong></td>
</tr>
<tr>
<td>0.33</td>
<td>+3.29</td>
<td>+4.22</td>
</tr>
</tbody>
</table>

If the drag coefficient is reduced from 0.44 to 0.34 (-22%), we could expect up to 3% fuel savings for the conventional and almost 4% for the hybrid. This is consistent with light duty fuel consumption reduction estimates which predict a 1.5% fuel saving for each 10% reduction in drag coefficient.

8.2.3 Rolling Resistance

Table 24: Impact of Rolling Resistance alone on Fuel Consumption for the Class 2b

<table>
<thead>
<tr>
<th>Rolling Resistance</th>
<th>Percent Fuel Saved for Conventional (%)</th>
<th>Percent Fuel Saved for Hybrid (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.007</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>0.00665</td>
<td>+0.57</td>
<td>+0.85</td>
</tr>
<tr>
<td><strong>0.0063</strong></td>
<td><strong>+1.18</strong></td>
<td><strong>+1.59</strong></td>
</tr>
<tr>
<td>0.0059</td>
<td>+1.82</td>
<td>+2.43</td>
</tr>
<tr>
<td>0.0058</td>
<td>+2.02</td>
<td>+2.69</td>
</tr>
</tbody>
</table>
Several rolling resistance improvements were considered and are described in Table 24. The value corresponding to a 10% rolling resistance improvement was chosen and could allow about 1.18% of fuel savings.

### 8.2.4 Transmission

<table>
<thead>
<tr>
<th>Gearbox</th>
<th>Percent Fuel Saved if reference is 6-Speed (Conventional)</th>
<th>Percent Fuel Saved if reference is 4-Speed (Conventional)</th>
<th>Percent Fuel Saved if reference is 6-Speed (Hybrid)</th>
</tr>
</thead>
<tbody>
<tr>
<td>6-Speed Automatic</td>
<td>0</td>
<td>+4.59</td>
<td>0</td>
</tr>
<tr>
<td>8-Speed Automatic</td>
<td>+1.72</td>
<td>+6.23</td>
<td>1.39</td>
</tr>
</tbody>
</table>

An 8 speed automatic transmission was selected as the improved technology. If the baseline is a 6-Speed automatic, only 1.72% of savings could be expected. However, if the reference vehicle is now equipped with a 4-Speed automatic gearbox, then the amount of fuel saved could reach 6.23%.

### 8.2.5 Engine

The modeling assumptions for the engine technology focused on the improvement of the efficiency through linear scaling of the entire map. Other technologies such as gasoline direct injection, turbo charging and downsizing could be considered but were not modeled.

<table>
<thead>
<tr>
<th>Engine Peak Efficiency (%)</th>
<th>Percent Fuel Saved for Conventional (%)</th>
<th>Percent Fuel Saved for Hybrid (%)</th>
</tr>
</thead>
<tbody>
<tr>
<td>34.7</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>35</td>
<td>+0.77</td>
<td>-</td>
</tr>
<tr>
<td>36</td>
<td>+3.54</td>
<td>-</td>
</tr>
<tr>
<td>37</td>
<td>+6.16</td>
<td>-</td>
</tr>
<tr>
<td><strong>38</strong></td>
<td><strong>+8.59</strong></td>
<td><strong>+8.86</strong></td>
</tr>
</tbody>
</table>

The peak efficiency was linearly scaled to match the improvement goal. If this value is increased from 34.7% to 38%, roughly 9% of fuel savings can be expected for both conventional and hybrid. For all the package simulations where engine improvement was applied, a 38% peak efficiency value was used.

### 8.2.6 Hybrid

The hybridization of the class 2b truck was assumed to be a parallel Hybrid Electric Vehicle equipped with a 50 kW electric machine. The features offered by such technologies are Engine Start/Stop
operations, regenerative braking, electric launch at low vehicle speeds and a blend of engine power and motor power depending on the Battery State of Charge.

Table 27: Impact of Hybridization on Fuel Consumption for the Class 2b

<table>
<thead>
<tr>
<th>Rolling Resistance</th>
<th>Percent Fuel Saved compared to Conventional(%)</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Parallel HEV – 50kW motor –</strong></td>
<td><strong>+14.81</strong></td>
</tr>
<tr>
<td><em>No change in weight</em></td>
<td></td>
</tr>
<tr>
<td>Parallel HEV – 50kW motor –</td>
<td>+13.94</td>
</tr>
<tr>
<td>+100Kg weight</td>
<td></td>
</tr>
<tr>
<td>Parallel HEV – 100kW motor –</td>
<td>+15.27</td>
</tr>
<tr>
<td><em>No change in weight</em></td>
<td></td>
</tr>
<tr>
<td>Parallel HEV – 100kW motor –</td>
<td>+13.42</td>
</tr>
<tr>
<td>+200Kg weight</td>
<td></td>
</tr>
</tbody>
</table>

Drive cycles such as UDDS or HWFET do not require a electric machine with a power greater than 50 kW in order to capture most of the braking energy. Consequently, the hybrid option with a 100kW electric machine was dismissed. The option which was chosen for package simulations was the 50kW electric machine with no change in weight.

8.3 Fuel Savings for Various Technology Combinations

In most cases, the sum of the fuel consumption benefits of individual technologies is greater than their combination. It is also interesting to notice that the fuel consumption reduction is always higher for the hybrid than for the conventional when the same technologies are applied.
Figure 43 shows an example of improvement package. In this case, a reduction in drag coefficient and weight is applied to both the conventional and the hybrid baseline vehicles. The sum of individual technologies either equals the combination (for the conventional) or is greater than the combination (for the hybrid). This figure shows that by combining a lighter weight with improved aerodynamics, fuel consumption could drop by 4 to 5%. For most technology improvements, the hybrid baseline benefits more from these changes than the conventional. If we take the example of the drag coefficient, this can be explained by the fact that reducing it not only lowers the vehicle aerodynamic losses but also lowers the energy provided by the motor and thus the battery will require less charging from the engine.
Figure 44 considers an additional improvement with the reduction of rolling resistance. In this situation also, the hybrid fuel savings are greater than for the conventional when looking at individual technologies or packages. The combination of a light weighted vehicle with low rolling resistance and improved aerodynamics could save between 5.5 to 6.6%.
Figure 45: Fuel Consumption Savings by combining Aerodynamics, Rolling Resistance, Transmission and Weight improvements on a Conventional and Hybrid Baseline.

Figure 45 adds the impact of an improved transmission to the previous figure. The percentage showed is for an 8-Speed transmission in comparison to a 6-Speed baseline vehicle. Since the reference vehicle has already an efficient transmission, this package does not reduce fuel consumption by a significant amount.

Figure 46: Fuel Consumption Savings by combining all improvements on a Conventional and Hybrid Baseline.
As showed by Figure 46, adding the improved engine efficiency to the combination package increases the fuel savings dramatically. This package can provide up to 15% fuel savings for the conventional and 16% for the hybrid.

![Impact of All technologies and Hybridization on Fuel Consumption](image)

**Figure 47: Fuel Consumption Savings by combining all technology improvements and hybridization on a Conventional Baseline.**

Finally, Figure 47 shows the impact of the full improvement package (including all the previous discussed technologies and the hybridization of the vehicle to a parallel HEV). This combination predicts a 28.4% fuel consumption reduction.

### 8.4 Comparison with TIAX Estimates

This section compares the fuel consumption reduction simulation estimates with the values generated by TIAX for the NAS committee.
In Figure 48, one notices that the main differences come from the transmission and the engine. TIAX used a 4-Speed transmission baseline vehicle whereas the simulation assumptions were based on a 6-Speed configuration. In addition, the engine improvements for simulation only focused on peak efficiency while TIAX considered more advanced technologies. On Figure 49 the same comparison is made where both simulation and TIAX use a 4-Speed baseline vehicle. Therefore, the only major difference between the two studies remains in the engine technology improvement. For all the other technologies, TIAX and PSAT estimates are not significantly different.
Figure 49: Fuel Consumption Savings of Improvement Package using Simulation or TIAX Estimates when using the same baseline Transmission.

The figure shows the percent fuel saved for different technology combinations (PSAT and TIAX) and their individual components (Hybrid CS, Engine, Transmission, RR, Cd, Weight). The graph indicates significant improvements with each combination, with some combinations showing a 44.5% fuel savings.
9 Conclusion

Numerous simulation studies were performed to provide quantitative inputs to support the National Academy committee recommendations. The simulation tool along with the vehicle and component assumptions was defined. Specific drive cycles were selected for the different applications considered.

The study of the different metrics pointed out to the need to use fuel consumption rather than fuel economy. In addition, the payload should be considered as well to properly represent the work of the truck. As such, some metric related to Load Specific Fuel Consumption seem most appropriate to evaluate truck technologies.

The energy / power analysis highlighted the importance of the engine losses compared to the rest of the drivetrain. In addition, the average vehicle speed should be carefully considered when evaluating a technology since its influence on fuel consumption will greatly differ.

While the average vehicle speed of a drive cycle correlates well with fuel consumption, the fuel consumed is always higher than during steady-state operations, especially for urban driving (low average speed). Since a particular technology might have different influence based on the vehicle weight, representing its impact of several payloads would allow a more accurate evaluation.

The impact of several individual technologies, both individual and cumulated, was assessed, including aerodynamic, rolling resistance, fuel type, transmission, engine and hybridization. The difference between the sums of each individual technology was compared with the gains of the cumulated technologies.

The study demonstrated the usefulness of vehicle modeling and simulation to assess the potential of numerous technologies for different drive cycles and operating conditions (e.g., payloads). However, because of the large number of applications and the fact that some vehicles are specifically designed for customers, there is currently no widely accepted Vehicle Technical Specifications – VTS - (e.g., maximum vehicle speed, grade, performance...) for each option. Since technologies should be compared based on similar VTS, the definition of the vehicle characteristics for powertrains such as HEVs becomes problematic. In addition, the limited access to specific state-of-the-art data for all applications leads to using component with similar technologies, which is non-ideal.
